Developing new evaluation methods in systemic lupus erythematosus

Monitoring systemic lupus erythematosus (SLE) requires comprehensive assessment of disease activity, comorbidities, chronic damage and patients’ perspective of the disease. This narrative review summarizes the innovative and currently available tools to assess SLE patients in clinical research and routine practice setting focusing on what is new in the assessment of disease activity and damage, discussing composite indices and organ-specific scores; a separate section is dedicated to the imaging techniques useful to assess neuropsychiatric, musculoskeletal and renal involvement. SLE-related chronic damage and comorbid conditions contributing to patients’ illness and long-term outcome are discussed. Finally, the impact of SLE on patients’ quality of life is addressed focusing on self-reported questionnaires, adherence to treatment and work ability.

Keywords: comorbidities • disease activity indices • imaging • self-reported outcome • systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease characterized by a heterogeneous range of clinical and serological manifestations both in individual patients and across the population. The disease course is variable, with alternate periods of flares and remission, and requires a long-term treatment to control disease activity and prevent chronic damage.

The recent recommendations for treat-to-target encompass 11 points to consider when approaching a patient with SLE. The achievement of remission or lowest systemic disease activity should guide the treatment in order to prevent flares and to limit the damage accrual [1]. The definitions of remission still need concrete efforts. The definition of low disease activity, that nowadays is adopted even in routine care to guide the treat-to-target strategies in rheumatoid arthritis, has been extended to lupus patients.

Very recently, a definition of Lupus Low Disease Activity State (LLDAS) has been proposed by the Asia-Pacific Lupus Collaboration group; the LLDAS definition is based on the evaluation of disease activity by a global score and physician assessment, and the medication status: an SLE Disease Activity Index (SLE-DAI) 2K score ≤4 without active involvement of major organ system, no new lupus disease activity since the previous assessment, a Physician Global Assessment < 1, a prednisone dose of ≤7.5 mg/day and stable and well-tolerated maintenance dose of immunosuppressants and approved biological drugs [2].

Besides the assessment of the disease status, the evaluation of SLE patients in clinical practice should not leave out the assessment of comorbidity – which reflect on long-term damage – and patients’ quality of life, including work ability.

The purpose of this narrative review is to summarize the innovative and currently available tools to assess SLE patients in clinical research and routine practice setting. The discussion focuses on the assessment of disease activity by clinical indices – including patient-reported questionnaire – and imaging techniques and the evaluation of chronic damage due to SLE and comorbid conditions.
What is new in disease activity assessment
Composite indices

The assessment of disease activity is a critical issue in a complex disease such as SLE, characterized by a huge clinical and laboratory heterogeneity. Several indices have been proposed to assess the treatment response in randomized controlled trials (RCTs) but they can be useful also to evaluate SLE patients in routine clinical practice.

Until recently, two different types of indices have been applied: the global score systems, such as the SLEDAI, providing an overall measure of activity, and the individual organ/system assessment scales, such as the British Isles Lupus Assessment Group (BILAG), evaluating disease activity in different organs. All the indices include both clinical and laboratory items, related to the disease manifestations (reviewed by Ceccarelli et al.) [3].

Table 1 lists the main disease activity indices with strength and limitations.

The recent development of biological drugs for the treatment of SLE patients determined the need for new indices in order to evaluate, more accurately and sensitively, their efficacy in RCTs. So far two composite indices have been proposed: the SLE Responder Index (SRI) and the BILAG-Based Composite Lupus Assessment (BICLA) [4–6]. SRI was employed for the first time in the BLISS-52 and BLISS-76 trials to evaluate the efficacy of belimumab [4,5]. The SRI provides the assessment of disease activity by using three components: reduction of SELENA–SLEDAI, no worsening in the BILAG domains nor in the Physician Global Assessment (PGA). The application of SRI allowed identifying a significantly higher percentage of responder patients in the belimumab arms compared with placebo [4,5]. More recently, BICLA index has been applied in the EMBLEM study, designed to evaluate the efficacy of Epratuzumab in SLE patients [6]. This newer index assesses the drug efficacy by investigating the modification of three items – no worsening in the SLEDAI-K and PGA and improvement in BILAG domains – and the absence of treatment failure [6]. The two composite indices assign different weight to SLEDAI or BILAG in the evaluation of disease activity reduction, with the SRI focusing on SELENA–SLEDAI compared with BICLA focusing on BILAG improvement. A limitation of SLEDAI is that it scores some items as present or absent rather than considering a continuous range; therefore, even SRI lack of the ability to detect minimal improvements; moreover, some organ manifestations are completely excluded by the SLEDAI. Indeed, the two available composite response indices include the physician evaluation of the disease activity to overcome the inability
of the global scores to cover every single SLE manifestation. The clinical trials investigating the effect of a new B Lymphocyte Stimulator – in other words, tabalumab – addressed the clinical response with a more stringent index, the SRI-5, which is centered on a 5-point reduction in SELENA-SLEDAI score. However, in the ILLUMINATE studies, the percentage of patients achieving the primary endpoint – SRI5 – was similar among the treatment groups leading to the interruption of Tabalumab program [7,8].

The SRI and BICLA differ from the LLDAS since these indices record the change in disease activity status from a baseline condition rather than identify a target for the treatment strategies.

**Single organ assessment**

The application of global activity index does not allow to assess all the manifestations of SLE. As for SLEDAI, the value obtained from the sum of the items identified in the different manifestations, both at a specific time-point and in the follow-up evaluation. The only exception is the renal component of the SLEDAI (R-SLEDAI) that allows to categorize patients with kidney involvement attributing four points to the presence of proteinuria, hematuria, urinary casts and pyuria; the R-SLEDAI score ranges from 4 to 16 [9]. These suggestions wish for the use of specific indices able to evaluate each organ/system involvement.

The Lupus Foundation of America-Rapid Evaluation of Activity in Lupus (LFA-REAL) is a clinical index still in development, based on an expanded version of PGA (separate PGA scores for each active organ system); this index allows to easily and quickly measure disease activity and response to treatment [10]. The LFA-REAL considers at least six single-organ on a 100 mm visual analog scale (VAS); only active organ requires scoring and more scales can be added to record manifestations not included in the first six (mucocutaneous, musculoskeletal, cardiorespiratory, neuropsychiatric, renal and hematological). The landmarks are the same as for the PGA: 0 = none, 1 = mild, 2 = moderate and 3 = severe [10]. In the preliminary evaluation, the LFA-REAL demonstrated a wider range of scores compared with BILAG, SLEDAI or PGA, especially at higher levels of disease activity; moreover, the LFA-REAL global and organ-specific scores showed significant correlation with SLEDAI, BILAG and PGA scores [10]. The LFA-REAL would be an easy tool to assess both global and single-organ disease activity in clinical setting.

Joint involvement is a frequent and heterogeneous manifestation, occurring in up to 90% of SLE patients. So far, no specific and validated indices to assess articular involvement in SLE patients are available. In a previous paper published by our research group, we proposed to evaluate joint involvement in SLE patients with Disease Activity Score (DAS) 28 [11]. This index has been validated and used in clinical trials and in routine practice in patients with rheumatoid arthritis. Assessing the DAS28 score in a cohort of 69 SLE patients with joint involvement, we were able to identify a subgroup of 48 patients (69.6%) with articular manifestations not captured by the SLEDAI-2K definition; moreover, 56.3% of this subgroup of patients had a moderate/high activity according to DAS28 values [11]. These results suggested the possible use of DAS28 index in the assessment of joint involvement in SLE patients, allowing higher sensitivity compared with the global index SLEDAI-2K [11].

Since there are no guidelines for the clinical diagnosis of cutaneous lupus erythematosus, the assessment of skin manifestation of SLE can take advantage of the Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI); this index was developed and validated for the first time in 2005 and revised in 2010 [12]. The revised version of CLASI provide a valuable tool to evaluate disease severity of different mucocutaneous manifestations taking into account the localization and extent of active (erythema, hyperkeratosis, infiltration and subcutaneous nodules) and chronic damage components (depigmentation and atrophy). The revised CLASI also assesses mucous membrane lesions and both scarring and nonscarring alopecia (i.e., diffuse alopecia and ‘lupus hair’) [12].

**What is new in the imaging assessment**

In the last years, several imaging techniques have been used to assess the different SLE manifestations. In particular, imaging modalities have been applied in order to evaluate musculoskeletal and neurological manifestations of SLE. More recently, some attempts have been made to assess patients with LN by using imaging tools.

**Neuropsychiatric involvement**

Neuropsychiatric involvement is one of major causes of morbidity and mortality in patients affected by SLE and is characterized by several different central and peripheral features. Their evaluation could be difficult and require to exclude all the other possible causes, such as medication side effects, infections or psychosocial-related conditions. In order to guide the clinician in the differential diagnosis, several imaging tools have been used to assess neuropsychiatric manifestations [13].

The imaging tool more frequently applied in the assessment of neuropsychiatric involvement in SLE
patients remains the conventional magnetic resonance imaging (MRI), able to identify modification both in the central and peripheral nervous systems [14]. In particular, MRI shows high sensitivity in the identification of focal findings such as cerebrovascular disease and myelitis (80–90%) [13]. Some data have suggested the possible use of MRI to assess cognitive dysfunction in SLE patients. In particular, the study recently published by Zimmerman and colleagues demonstrated a reduced temporal lobe structure in SLE patients with cognitive dysfunction compared with those without cognitive deficits [15]. Moreover, MRI could be used to longitudinally assess SLE patients: in a recently published study, the MRI evaluation at baseline and after 20 years of follow-up demonstrated the progression of MRI brain damage in SLE patients independently from neuropsychiatric involvement; moreover, this progression seemed to be associated with increased risk of new events [16].

In the light of the observation that more than a half of patients diagnosed with neuropsychiatric manifestations have a normal MRI of the brain, other imaging modalities have been investigated [13]. In particular, the single photon emission computed tomography (SPECT) has been used to assess specific disease-related manifestations. SPECT imaging provides an estimate of regional cerebral blood flow and neuronal integrity but the results deriving from its application seem to be inconsistent, suggesting the possible use of this imaging tool exclusively as MRI complementary evaluation [14].

**Renal Resistive Index & lupus nephritis**

The identification of markers of severity and activity able to guide clinicians in the choice of the most appropriate treatment is a critical issue in the assessment of LN patients. The Resistive Index (RI) is an ultrasonographic parameter, easy to perform, integrating data about the arterial compliance, pulsatility and peripheral resistance. The increase of RI has been described in several kidney diseases, such as hemolytic uremic syndrome, renal vein thrombosis and allograft rejection [23].

To date, few data are available in the literature concerning the assessment of RI in LN patients. In a recent paper we studied 42 LN patients requiring kidney biopsy: we identified a significant association between the presence of a pathologic RI value and the histologic class IV glomerulonephritis, widely recognized as the most severe [24]. Moreover, we detected an association between the pathologic RI and the presence of specific histologic glomerular findings (synechiae and cellular-fibrotic crescent formation); these results could suggest the possibility to use the RI as a marker of severity in LN patients [24]. Further longitudinal studies are needed in order to evaluate the possible prognostic role of this index. More recently, we also evaluated the RI in a cohort of patients with antiphospholipid syndrome (APS), comparing 13 patients with primary APS and 23 APS-associated APS [25]. The almost exclusive association of a pathologic RI with secondary APS and the presence of renal artery stenosis only in patients with primary APS, might suggest a role of anti-phospholipid antibodies in determining the stenotic–thrombotic–lesions detected in the primary APS whereas mTORC could be involved in the increase of RI observed in SLE-associated APS patients [25].

**What is new in the assessment of damage**

The increase of survival in SLE patients determined the risk to accrual irreversible organ damage. As under-
ligned by the treat-to-target recommendations, the prevention of damage is a major outcome in the management of SLE patients.

**Disease-related damage**

The presence of chronic damage in SLE patients and its modifications overtime can be evaluated by using a specific index, the Systemic Lupus Collaborating Clinics Damage Index/American College of Rheumatology Damage Index (SDI) [26]. The SDI has been widely applied in large SLE populations identifying the association between chronic damage and specific demographic factors, clinical features and disease activity. Adverse events of treatments, disease activity and comorbidities seem to be the major risk factors associated with damage development [27]. Concerning the treatment, the use of glucocorticoids is associated with the development of adverse effects, such as osteoporosis, diabetes mellitus, cataract and avascular necrosis, all included in the SDI. During the first years of the disease, the chronic damage could be defined as possibly or definitely steroid related in more than 50% of the SLE patients [27].

Conversely, several data confirmed the protective role of hydroxychloroquine in chronic damage development: the long-term assumption of this drug was associated with lower SDI scores and significantly prolonged damage-free survival in SLE patients [27].

Recently, the Lupus Damage Index Questionnaire (LDIQ), a self-administered patient-reported tool assessing the 56 items of the original SDI, has been proposed in SLE patients, showing a significant correlation with SDI [28]. A shorter questionnaire, the Brief Index of Lupus Damage (BILD), including only 26 items, has been more recently developed, demonstrating content, criterion and construct validity [29]. However, since its publication, the BILD was used only in few studies and it is not yet possible to draw any conclusion about its ability to capture chronic damage progression.

Moreover, the presence of specific autoantibodies, such as antiphospholipid (aPL) and anti-dsDNA, could be considered as a predictive factor for the development of chronic damage [30]. The association between chronic damage and aPL prompted the development and an initial validation of a chronic specific for APS patients (Damage Index in APS – DIAPS) [30]. The first study applying this index demonstrated the content, criterion and construct validity of DIAPS; however, further studies are needed to fully evaluate the possible application of this index in the clinical practice.

**Comorbidities**

The eleventh bullet point in the treat-to-target in SLE states: “relevant therapies adjunctive to any immunomodulation should be considered to control comorbidity in SLE patients” [1].

Recognition of comorbidity in SLE patients may be influential in determining treatment strategies and risk factor management. The Charlson Comorbidity Index (CCI) was developed to identify conditions associated with increased mortality [31]. The index includes 19 items and provides a summary cumulative score [31]. The impact of CCI was tested on SLE patients in two large populations long-term followed-up demonstrating an association between comorbidity score and mortality, regardless the age, disease activity and SDI score [32]. As expected, cardiovascular disease (acute myocardial infarction, congestive heart failure, cerebrovascular and peripheral vascular disease) accounted for about a third of comorbid conditions associated to SLE in the two cohorts evaluated [33]. Indeed, premature atherosclerosis is a well-recognized comorbidity in SLE and it is associated with increased mortality [33,34]. The European League Against Rheumatism (EULAR) recommendations for monitoring patients with SLE, suggest the need for monitoring traditional cardiovascular risk factors and treating modifiable risk factors according to the existing guidelines [35,36]. Besides the traditional risk factors, the role of SLE-related risk factors is well established [37]. The routine assessment of disease-related markers of atherosclerosis may help to stratify patients according to their cardiovascular risk burden and to elaborate preventive strategies. Anti-phospholipid antibodies, especially anti-β2 glycoprotein I (β2GPI), seem to represent an additional factor when evaluating the risk of atherosclerosis since the β2GPI-specific T-cell reactivity is associated with subclinical atherosclerosis [38].

Fatigue and widespread pain are debilitating symptoms with a negative impact on the quality of life of SLE patients. Up to 90% of SLE patients refer fatigue and 50% of them consider it the most disabling symptom [39]; fibromyalgia, as a cause of generalized pain, is reported by 5–22% of SLE patients [40–43]. Recently, a close association between SLE and fibromyalgia has been demonstrated: fatigue and widespread pain has been reported in 80% of SLE patients and in 33% of them fibromyalgia has been diagnosed [44]. Interestingly, no correlation has been detected between fatigue and disease activity suggesting an independent role for fibromyalgia as a comorbidity accounting for fatigue and pain that should be evaluated and managed separately in SLE patients [44].

More recently, the Pain Inventory-Short Form (BPI-SF) has been tested on SLE patients [45]. This is a self-assessment tool measuring several dimensions of pain (pain quality, pain relief, patient’s perception of pain) and able to depict the overall severity of pain as well as
its impact on patients’ health [45]. BPI-SF originated for the assessment of cancer pain and consists of four items investigating the severity and seven items that impact of pain, each ranging from 0 to 10; the two scores resulting from the mean of severity and impact domains are computed in mean total score. Naegele et al. concluded that BPI-SF is valid, reliable and psychometrically robust enough to evaluate pain in SLE patients [45].

**What is new in the assessment of self-reported outcome**

**Quality of life**

As reported in the treating-to-target recommendations, the assessment of “factors negatively influencing health-related quality of life (HRQoL), such as fatigue, pain and depression” should support the control of disease activity [1]. Indeed, the alternation of flare and period of low disease activity affect the quality of life of SLE patients.

The concept of HRQoL has been widely used to indicate the disease impact on the physical and psychosocial aspect of patient’s life caused by the physical and biological changes produced by the disease and by its treatment. For many years, generic questionnaires, applied for different chronic diseases have been employed to assess QoL in patients with SLE. Among these, the generic Short Form (SF)-36 was the most widely used. However, the evaluation of large cohorts of SLE patients detected a poorer QoL in SLE patients compared with healthy controls [46].

After the long-term use of nonspecific indices, more recently, specific questionnaires have been proposed for SLE patients. Among these, the LupusQoL is a questionnaire first developed and validated in the UK and subsequently validated in other languages [47,48]. The questionnaire, specifically designed for SLE patients, includes 34 disease-specific items and eight domains able to investigate specific aspects of the health status, such as sleep, fatigue, intimate relationship and body image. The Italian version of the LupusQoL was validated in a large cohort of adult SLE patients [49]. The analysis included 117 patients identifying a convergent validity between LupusQoL and the equivalent items of the SF-36. Moreover, the LupusQoL seemed to be able to discriminate the different degrees of disease activity as measured by the SLEDAI-2 K [71]. In fact, SLE patients with higher disease activity, defined as SLEDAI-2K ≤ 4, showed poor QoL compared with subjects with lower disease activity, with significant differences in physical health, planning, burden to others and fatigue items [49].

The Patient Acceptable Symptom State (PASS) is a feasible and time-sparing tool useful to assess patients’ status in the routine clinical practice recently tested in SLE patients. PASS is a single-question outcome tool to evaluate the level of symptoms at which patients consider themselves well, previously used to assess patients with inflammatory arthropathies and osteoarthritis, demonstrating a significant association with disease activity [50,51]. PASS question has been administered to 165 consecutive SLE patients demonstrating an acceptable clinical state in 80% of subjects [52]. In addition, PASS seems to be able to discriminate patients with different disease activity, as shown by the significantly lower mean SLEDAI-2K and ECLAM values in patients with an acceptable status compared with the others; moreover, active musculoskeletal involvement seemed to influence the status acceptability [52].

**Adherence to treatment**

Adherence – the extent to which a person’s behavior coincides with medical or health advice – is often poor in chronically ill patients. Different methods have been proposed to evaluate treatment adherence in SLE patients: self-reported, pill count, electronic monitoring (reviewed by Costedoat-Chalumeau et al.) [53]. The methodological discrepancies among the studies performed on SLE patients do not allow drawing any conclusion about the best method to address this issue; only few studies used specific, validated questionnaire, the most reliable and useful screening tool for nonadherence in clinical setting [54,55]. However, it is unanimous that the lack of treatment adherence may reflect on disease activity [56]. Therefore, more effort should be dedicated, even in routine clinical practice, to investigate and manage nonadherent behavior.

**Work ability**

The increase survival of SLE patients determined the need to evaluate other disease-related aspect such as the work disability. This is an interesting topic, in the light of the possibility to consider this parameter as a clinical outcome measure that could be followed over time.

The assessment of work ability has been performed by using self-administered questionnaires, evaluating the inability to work. Several data demonstrated an increase of work disability rate in SLE patients, ranging from 20 to 50% [57]. Moreover, about a third of the SLE patients become work disabled within 3–12 years from the disease onset. A multifactorial etiology could be considered for work disability and several factors have been related to the development of inability to attend work. Among these, some disease-related factors, such as disease duration, activity and chronic damage and cognitive dysfunction, but also other not specifically related, such as age, ethnicity,
Conclusion
Clinicians involved in the management of SLE should be aware that a global assessment is essential for this multifaceted disease; disease activity and damage accrual should be evaluated at each visit in every single patient. Nowadays, several tools are available both in research and clinical practice settings. The response indices used in RCT failed to capture modest change in disease activity – and may have somehow contributed to the negative results of the clinical trials – and seem not to detect minimal clinically significant improvement that may be relevant in daily clinical practice. These new tools developed to evaluate treatment response could be not the best way to assess the improvement of the disease, reflecting the limitations of the indices included in the composite score. Moreover, in a routine setting, the use of some indices may be not always feasible and time effective – as in the case of BILAG and BILAG-based indices; on the other side, the simpler evaluation of SLEDAI score might overlook some manifestations not included in the index and is not able to differentiate/grade different severity within the same item. Even if the evaluation of SLE patients is not yet standardized and no one of the activity index can be currently considered a gold standard, the SLEDAI score seems to be useful in research and clinical setting when included in a more comprehensive evaluation of SLE patients.

Newer indices and questionnaires are currently under investigation to simplify and quicken the assessment of SLE patients. Besides disease activity and chronic damage, a comprehensive evaluation should never overlook quality of life and comorbidities, in low educational level and socio-economic status [57]. Some SLE-relevant manifestations are more associated with work disability; in particular, incident thrombosis and musculoskeletal manifestations determined an increased risk of work disability [58]. A longitudinal assessment should be considered an important topic in the work disability evaluation, in order to prevent its development [58]. In addition to the assessment of work disability, a recent study evaluated the absenteeism among SLE patients: an increased absenteeism was documented with an average deficit of 2.7 h/week [59].

Executive summary

- The treat-to-target strategy was recently extended to systemic lupus erythematosus (SLE). In this light, much efforts are dedicated to the definition of treatment goals such as remission and low disease activity.
- Lupus patients should be comprehensively evaluated for disease activity, chronic damage and co-morbidities; patients’ perspective should never been overlooked.
- Besides the single organ system scores, newer composite indices – SRI and BICLA – have been recently used to assess the treatment response in randomized clinical trials; these indices are based on SLEDAI and BILAG scores and include the physician assessment of to overcome the limitations of the two disease activity scores.
- The evaluation of single organ involvement is still limited by the lack of specific indices with the exception of skin and kidney that can be scored by renal component of SLEDAI and CLASI. LFA-REAL is a single-organ evaluation tool which scores only active involvement in mucocutaneous, musculoskeletal, cardiorespiratory, neuropsychiatric, renal and hematological domains with more scales added to record manifestations not included in the list.
- Imaging techniques have been used to assess different SLE manifestations including musculoskeletal (Doppler ultrasound) and neurological features (magnetic resonance). More recently, some attempts have been made to assess patients with kidney involvement by using imaging tools: the Resistive Index is an ultrasonographic parameter integrating data about the arterial compliance, pulsatility and peripheral resistance which has been proposed also for lupus nephritis patients.
- Besides the SLICC Damage Index, a self-administered questionnaire – the Lupus Damage Index Questionnaire – and its brief form, have been proposed to assess the chronic damage accrual. The patient-reported questionnaire demonstrated a good correlation with the SDI.
- The eleventh bullet point of the treat-to-target in SLE concerns the adjunctive therapies to control comorbidities; the Charlson index seems to be a useful tool to evaluate concomitant disease in SLE patients. The routine assessment of traditional and disease-related for atherosclerosis could help stratifying patients according to their cardiovascular risk burden and to elaborate preventive strategies. Moreover, fatigue and widespread pain is reported by a high percentage of SLE patients and an association with fibromyalgia should be not ignored considering its impact on patients’ quality of life.
- The assessment of ‘factors negatively influencing health-related quality of life’ should support the control of disease activity. In this light, generic or disease-specific questionnaire evaluating the impact on the physical and psychosocial aspect caused by the disease should be included in the comprehensive evaluation of SLE patients. Moreover, adherence to treatment and work ability should also be investigated.
order to stratify patients according to disease severity and predict long-term outcome.

Future perspective
The age of biological drugs for SLE treatment has coincided with the appearance of more sensitive outcome measures able to capture the treatment effect. Actually, the limits demonstrated by the composite indices in the RCT may suggest to assess separately the different organ involvement with more accurate scoring systems. Besides the need for alternate outcome measurements sensitive even to minimal clinically important change in research setting, the treat-to-target approach will further extend to the management of Lupus patients in clinical setting; in the absence of defined outcome states, more efforts will be dedicated to define remission and low disease activity, achievable goals of the treatment of SLE patients. Moreover, more efforts are still needed to identify sensitive and reliable biomarkers of SLE, both systemic and organ-specific.

Review

Therapeutic targets in psoriatic arthritis

Despite their common use in treating psoriatic arthritis, there is little evidence supporting the use of conventional disease modifying agents such as methotrexate. Although treatment with inhibitors of TNF-α has brought significant benefit to certain patients with PsA, many do not respond. TNF-α inhibitors have also demonstrably failed to prevent new bone formation, a critical aspect to the changes in PsA that ultimately leads to joint destruction and disability. The identification of several new targets in PsA, and the advent of recently approved compounds inhibiting these targets, heralds a new dawn for PsA. The differential relevance of targets in rheumatoid arthritis and PsA underlines the need for a paradigm shift in how we name, describe and categorize rheumatic diseases.

Keywords: IL-17 pathway • molecular network • novel therapy • psoriatic arthritis

General considerations

Much has been learnt by the success of highly specific cytokine targeting, using biologic agents, in specific inflammatory diseases. However, even more has been learnt by noting the failure of these same agents in other inflammatory conditions, especially in instances where the responsive and the unresponsive diseases are thought to have a biological kinship. If Moll and Wright had difficulty persuading their colleagues at the time, of the existence of a phenotypically distinct entity to rheumatoid arthritis (RA) which we now know as psoriatic arthritis (PsA), their case would have had no adversaries today. The clinical phenotypic expression of PsA is now recognized to be quite different to that of RA. This is true at the microscopic level as well as during synovial examination with an arthroscope, where differing cellular infiltrates and vascular patterns are recognized [1,2]. More importantly, however, RA responds to a number of very specific cytokine blockades, where PsA does not (e.g., IL-17 antagonism). This underlines the importance of a varying cytokine hierarchy in the differing disease networks.

There is now a strong case to be made for developing a taxonomy of diseases (inflammatory and others) based not on clinical features, but rather on a more meaningful biological basis. This might begin with examining the varying levels of importance of certain cytokines in a given pathology [3]. A more advanced nomenclature and classifications approach would develop from a clinically and biologically meaningful system, based on a complete understanding of the disease networks [4].

The dawn of new era for PsA

Before late 2013, the last drug to be approved in Europe targeting a novel pathway in PsA was leflunomide, and even this was as far back as 1999. Furthermore, this was not itself a novel agent, simply an extension of existing licensed indications. Therefore, although it is true that over the last 15 years there have been additional agents targeting the TNF-α pathway, agents targeting truly novel pathways in PsA have been lacking. Both the European
Medicines Agency and the US FDA recognize that for those with PsA who have not responded adequately to TNF-α inhibition (TNFi), there are few alternatives. However, these past 18 months have seen two truly novel compounds meeting licensing requirements and reaching market, and at least one agent very likely to meet approval in the near future. All this makes for an exciting new era in the treatment of PsA.

Is PsA an important pathology?
PsA is the second most common inflammatory arthropathy [5], and it is now recognized that it is still both under recognized and under treated [6,7]. To address this, efforts have been made to improve recognition of PsA [8]. Since psoriasis precedes PsA in approximately 80% of cases, many of these efforts focus on the inflammatory dermatology clinics [9,10]. Importantly, PsA most frequently affects young people, with most studies reporting an age of onset in the 4th decade of life [11–13]. Quite apart from the short and medium-term deleterious effects of PsA on patients, as evidenced by measurements of pain and mental well-being, the disease itself is inherently destructive to bone, cartilage, enthesis and other soft tissues [14,15]. Furthermore, patients with PsA also have reduced longevity, principally due to increased cardiovascular mortality [16].

Understanding that PsA has a destructive nature is important, as failure to achieve satisfactory abrogation of the aberrant inflammatory response, may result in disability, with further implications for quality of life and the ability to remain in employment. In fact, patients with PsA have similar HAQ scores (a validated measure of disability) as patients with RA [17]. There is now some evidence suggesting that the same ‘window-of-opportunity’ exists early in the natural history of PsA as in RA, and it is therefore becoming increasingly important to treat these patients as quickly as possible after the diagnosis has become established [6].

Why is there a need for novel targets?
PsA has been shown to be painful, destructive, disabling, and patients have a decreased life expectancy. The disease is, therefore, not dissimilar in many of these parameters to RA, but in RA, B-cells, IL-6 (IL-6) and the T-cell co-stimulatory molecule CD80/86, have all been shown to be relevant targets that have been exploited by approved biological therapies. In PsA, none of these agents have been approved. Despite the presence of B-cells in abundance in the synovium of patients with psoriatic arthritis [18], the results of an initial pilot study of rituximab in PsA was disappointing. No clinical trials have yet been performed evaluating tocilizumab for PsA, but there are a number of case reports with varying results [19–21]. There is already some evidence to support the use of abatacept to treat patients with PsA. In a phase IIb study of abatacept in PsA, a 3 mg/kg dose was associated with better skin response, while 10 mg/kg dose (the dose approved for RA) was associated with better ACR20 response [22]. Abatacept is now being studied, delivered subcutaneously, in a Phase III trial.

It is also worth noting that the primary outcome for most RCTs in PsA is ACR20, a very modest treatment benefit, and only 40–60% of patients achieve this.

PsA is, therefore, a significant burden to patients and a costly disease to the wider healthcare system, but has not been witness to the expansion of drugs with novel targets that RA has been the beneficiary of. Indeed, existing first-line therapies for PsA such as methotrexate and leflunomide lack an evidence base from randomized controlled trials (RCTs) [23].

Immunopathogenesis of PsA
The centrality that TNF-α and related Th1 response cytokines have in the immunopathogenesis of PsA is well recognized and exploited by targeted therapies. TNF-α is a critically important cytokine in PsA, and its presence has been demonstrated in the inflamed synovium, the enthesis, as well as in psoriatic skin [24,25]. TNFi has offered the most significant advance in treatment of PsA witnessed to date. TNF-α appears to be a key player operating as a ‘node’ in the disease network, and is responsible for the production of several other proinflammatory cytokines including IL-1, IL-6, IL-8 and IL-12, although it appears that these cytokines play a more minor role in the PsA phenotype than in the RA disease network [3,26,27].

The most promising novel targets that have been identified over the last decade concern protagonists in the IL-6 and the IL-23/IL-17 pathways.

IL-17 was first identified as inducing the production of IL-6 and IL-8 in human RA synoviocytes and skin fibroblasts from normal individuals, betraying its inherent proinflammatory characteristics [28,29]. It was then demonstrated that IL-17 was produced by RA synoviocytes, and that blockade in vitro (using specific IL-17 monoclonal antibody) could significantly reduce the production of IL-6 [30]. This set of experiments also demonstrated an important relationship concerning synergy between cytokines. In this case, it was observed that IL-17 must be in the presence of IL-1 and TNF-α, to maximize production of IL-6 [31]. The signaling of IL-17 through its major receptor (IL-17RA) is unique because it does not utilize JAK and STAT pathway, instead favoring an association of receptor with adaptor protein ACT1. The binding of IL-17 to its receptor thus activates NF-κB [32,33]. Quite apart from...
from increasing proinflammatory cytokine expression in this manner, IL-17 receptor activation results in the stabilization of mRNA encoding for growth factors and chemokines \([34,35]\).

A major source of IL-17 is a set of helper T cells quite distinct from the classical Th1 and Th2 types, known as Th17, after their signature cytokine \([36,37]\). These cells do not produce IFN-\(\gamma\) or IL-4, thus distinguishing them from classical helper T cells. Their differentiation from naive T cells to specific Th17 cells is more complicated than originally thought. IL-23 increases the levels of IL-17 in naive T cell culture \([38]\), but there is no IL-17 receptor on naïve T cells. However, it has become clear that IL-23, which is produced by activated dendritic cells, is nonetheless important in TH17 cell differentiation, but that it is not the only pathway supporting this differentiation.

IL-23 is closely related to IL-12, sharing a common p40 subunit. Given the known importance of IL-12 in Th1 responses, it has been thought that targeting the shared p40 subunit may abrogate both Th1 and Th17 responses.

One theoretical attraction of this axis is the realization that this pathway can lead to the expression of all four features typical of psoriatic arthritis: skin and joint inflammation, erosive bone disease and pathological new bone formation. Thus by inhibiting the IL-23/17 axis at any of several levels, improvements in each parameter may be expected (see Figure 1).

**TNF-\(\alpha\)**

There are now five TNFi agents approved in Europe for PsA, and their efficacy in treating the disease has a good evidence base, whether used with or without conventional DMARDs \([23,39,40]\). However, despite the availability of five individual TNFi, collectively they target a single pathway, and there is no evidence to support significant differences in their efficacy on articular, enthesial or axial disease, or indeed any major differences in safety profiles \([41–44]\).

The use of TNFi has the additional benefit of efficacy in treating spinal symptoms where conventional DMARDs show little efficacy \([45]\), however, whether this symptomatic improvement is reflected in a true retardation of the destructive process in the axial spine is contested. There certainly appears to be a reduction in axial inflammation as evidenced by decreased pain, decreased acute phase reactants and greater lumbar spine flexibility, but the progression of radiographic findings is a more complicated matter.

One important consideration regarding the use of TNFi in PsA relates to the differences observed in bone changes between RA and PsA, in the natural history of the respective diseases. In contrast to RA where only erosive changes are seen in bone, both anabolic and catabolic effects on bone are observed in PsA, and can be assessed using widely available imaging modalities.

Firstly, the bone erosions are architecturally distinct in PsA where the erosions are themselves associated with new bone formation, resulting in smaller erosions with significant periosteal bone proliferation, thereby giving them an ‘inverted omega’ appearance \([46]\). Secondly, new bone formation also tends to occur at the site of the enthesis, distal from the erosive sites. The effects of the new bone formation in PsA must at least be considered of equal importance in the development of functional impairment as the development of erosions. For example, in severe cases proliferating bone develops over the entire circumference of a small joint, giving the appearance of the so-called ‘bony corona’ on imaging, and resulting in significant disability \([47]\). In addition, since the enthesis is the principal site of new bone formation, and is also the junction where inflamed periarticular tissue and the bone surface meet, changes here effecting the attachment of tendons and their muscles to bone can lead to significant disability \([48]\).

We concentrate here on the anabolic effects observed in PsA, because it is increasingly recognized that preventing this will be as important as preventing erosive disease in treating PsA. However, the TNFi have consistently failed to demonstrate any efficacy in achieving a reduction in the progression of new bone formation, and this is now seen as a significant failing of TNFi \([47]\). Moreover, radiographic scores in PsA focus on bone erosions, and will need to address the issue of new bone formations as well \([49]\).

There is a clear biological basis for the lack of efficacy of TNFi on new bone formation. While TNF-\(\alpha\) promotes osteoclast differentiation by inducing the expression of receptor activator of NF-\(\kappa\)B ligand in the joints \([50]\) (the essential differentiation factor for osteoclasts), it is also a potent suppressor of osteoblast differentiation \([51]\).

Consist with this biology, the antagonism of TNF-\(\alpha\) in PsA does not retard new bone formation \([46]\), and indeed similar results are seen in ankylosing spondylitis (AS), where new bone formation has long been understood to be an important pathological process \([52,53]\). The importance of IL-22 in promoting new bone formation via activation of STAT3 and subsequent upregulation of genes regulating bone formation has only recently begun to be understood, and thus far, no agents have specifically targeted this pathway \([54]\).

However, one report over a longer period of time (8 years) in AS, with a retrospective design and small numbers, suggests there may be less new bone growth in those treated with TNFi \([55]\).
IL-12/-23

Our understanding of the pathophysiology of PsA, and in particular the recognition of role that the IL-17 and IL-12/-23 axis plays, has provided for an exciting...
era in treating PsA. Indeed, it is this pathway that has provided the first new biologic target in PsA since the advent of TNFis, in the form of ustekinumab, and this brings with it the potential promise of further agents to come.

Ustekinumab is a fully human monoclonal antibody that binds to the common p40 subunit of IL-12 and IL-23. IL-12 is a key cytokine in the Th1 inflammatory response, and IL-23 is involved in the activation of Th17 cells and the subsequent production of IL-17. There is evidence that IL-23 is essential for enthesitis to develop by acting on a specific T-cell subset. This subset, (IL-23R(+), RAR-related orphan receptor γt (ROR-γt)(+)CD3(+CD4(-)CD8(-), stem cell antigen 1 (Sca1)(+)) was identified at the entheseal insertion in an animal model of enthesitis by Sherlock et al., and this finding underlines the importance IL-23 may have as a target in PsA [54]. These cytokines occupy an important place in the inflammatory network of PsA.

The efficacy and safety of ustekinumab in patients with PsA has been established in the PSUMMIT1 trial in patients naive to TNFi [61]. However, arguably more importantly, in PSUMMIT2 clinical efficacy was demonstrated in those who have not responded to TNFi. In PSUMMIT2, most patients who have been included in the TNF experienced arm of the study discontinued TNFi because it was ineffective (between 64 and 72%). In fact, the majority of these patients had previously been on at least two TNFi, and 25% had been on 3 TNFi. Just over a third (35.6%) of patients who were TNFi experienced went on to achieve an ACR20 response. Although somewhat less than the results of TNFi naive patients (46% meeting ACR20 in PSUMMIT1 and 54.4% in PSUMMIT2), it is likely that this cohort represent more recalcitrant disease, or perhaps a subset of PsA patients whose disease is phenotypically distinct and not primarily driven by TNF-α. On the strength of these studies both the EMA and the FDA have approved ustekinumab for treatment of PsA, at last providing an option (and truly novel target) for those with PsA who have not responded to TNFi.

Safety data regarding ustekinumab was available from studies of its use in psoriasis (PsO), with no new signals emerging from the study of ustekinumab in PsA. However, the duration of the trials limit a definitive conclusion in relation to potential long-term effects, and these questions can only be answered by post marketing surveillance by the biologic registries.

The question of radiographic progression in those treated with ustekinumab is also partly addressed by the two trials, where radiographic data were analyzed together demonstrating that, at 24 weeks, ustekinumab decreases radiographic progression as measured by the PsA modified vdH-S scoring method [62]. The planned integrated analysis was reported using data from the two studies together because radiographic outcomes required higher numbers to be enrolled to be appropriately powered. This is a challenge in clinical trials where the primary or secondary outcomes are measured by radiographic scores over a relatively short period of time. However, there are important points to note here; again no radiological study examining axial progression is reported, and the scoring method of plain films of hands and feet is imperfect, not taking full account of new bone formation [49]. In the end, only long-term follow will be able to make a determination as to whether inhibition of IL-12/IL-23 can retard new bone formation, and have a truly disease modifying effect on the axial skeleton.

IL-17

Secukinumab is a fully human anti-IL-17A monoclonal antibody, already licensed for psoriasis in Europe earlier this year. Importantly, secukinumab at two doses performed better than etanercept for psoriasis in the FIXTURE head-to-head trial [63]. This is not only important from a drug selection and marketing point of view, but also informs us on the hierarchy of cytokines in specific inflammatory diseases, although we cannot extrapolate anything from this in relation to PsA.

There is now a growing body of evidence to suggest that secukinumab is efficacious in PsA. An initial small proof-of-concept study including 42 patients for 24 weeks, although failing to meet the primary endpoint (ACR20 at week 6), reported significant improvements in secondary outcomes [64]. The subsequent FUTURE 1 and 2 phase III RCTs have met their primary endpoints of ACR20 response at week 24, FUTURE1 demonstrating a 50.5 and 50.0% ACR20 response to secukinumab at 75 mg and 150 mg, respectively, and FUTURE2 demonstrating 29.3, 51.0 and 54.0% ACR20 response for doses at 75, 150 and 300 mg, respectively, versus 15.3% for placebo [65,66].

The two studies differed in their methodology for loading doses, as well as in subsequent dosing regimen, which may in part account for the differences in response rates seen at the 75-mg dose between the two studies. Data presented at EULAR’s annual congress in 2015 reported on response rates to secukinumab in patients naive to prior treatment with TNFi, compared with those TNFi nonresponders. As might be expected, better responses were seen in the naive group overall. Only those TNFi nonresponders receiving the 300-mg dose saw a statistically significant benefit when compared with placebo [67]. Notwithstanding the problems reporting radiographic outcomes in PsA discussed earlier, further data suggest that secukinumab may be able to retard
certain aspects of radiographic progression in PsA [68]. A host of secondary outcomes of these two trials have also been presented. The safety was similar to the data in psoriasis. Most adverse events related to upper respiratory tract infections, which were only slightly increased in incidence in the secukinumab arm, without an apparent dose relationship. Importantly no cases of tuberculosis were reported. Candida infections were more common in the secukinumab group, perhaps highlighting the importance in IL-17 host defense against fungi.

Two other monoclonal antibodies, brodalumab targeting the IL-17 receptor, and ixekizumab targeting IL-17A, have also been shown in short phase II studies to be significantly beneficial in plaque PsO [69,70]. Early data on the efficacy of brodalumab in PsA is now available with the results of an open label extension to the phase II study of brodalumab. During the Phase II trial period (to week 12), ACR20 responses were similar in the two studied doses (37 and 39%), and in the extension phase to week 108 this response was maintained [71]. Studies of ixekizumab in PsA are awaited.

Some have been disappointed by the observation that exploitation of these novel targets do not improve on ACR responses of TNFi. One possible theoretical reason for this may be the considerable level of redundancy in the individual cytokine pathways, such that when one target is blocked, other cytokine pathways that remain uninhibited perpetuate the inflammatory response. One potential strategy to circumvent this problem of redundancy may be to rationally combine agents so that more than one molecular target is inhibited. However, where this has been attempted in RA, the results of combining anakinra with etanercept perhaps surprisingly, failed to yield an improvement in efficacy compared with monotherapy with etanercept, and the occurrence of infections was significantly increased [72]. Similarly, combination treatment with abatacept and etanercept also failed to improve efficacy, with a similar marked increase in infection incidence [73]. While these studies were in RA, there is no biological basis for a belief that there would be any difference in PsA. Perhaps what we witness as frustrating redundancy in our attempts to abrogate inappropriate inflammatory responses in PsA, actually represents important failsafe immune mechanisms in host protection. In this manner, blockading two cytokines such as TNF-α and IL-1, which have broadly similar effects, will not increase efficacy of treatment, but could predictably increase incidence of infections [74].

**Other cytokines**

There is no doubt that other cytokines appear to be important in PsA pathogenesis, but their apparent presence at the scene of the crime is not necessarily indicative of their relevance as a therapeutic target. Clearly studies with both rituximab and tocilizumab, and to a lesser extend abatacept, have shown disappointing results, making B cells, IL-6 and T cells a less promising set of targets. Why biologically plausible targets, present at important sites at such abnormally high concentrations should not offer relevant approaches, is currently unclear, but may owe to our incomplete understanding of the disease network.

There may be some case for considering redressing the balance of differential T cell activation in PsA. Recent data suggest that IL-4 (the prototypical Th2 cytokine) can reduce levels of proinflammatory cytokines when lesional psoriatic skin is cultured in the presence of IL-4, although the mechanisms appear to be more complicated than simply induction of the Th2 response [75].

**Small molecular inhibitors**

Apremilast is a small molecular inhibitor (compounds with a molecular weight of less than 1 kDa) licensed in Europe since February 2015, and it constitutes another major advance in the treatment of PsA. Small molecular inhibitors have the benefit of being delivered orally, and are expected to be produced at a much lower cost that biological compounds [76]. Their targets in inflammation are usually intracellular signaling, principally kinases, which represent an attractive therapeutic target. These kinases act upstream of mediators such as TNF-α, and thus selective inhibition may inhibit several inflammatory processes [77,78]. The most notable success in this regard has been tofacitinib, where efficacy in RA has been established, and the agent is licensed in the USA (but not in Europe) for this indication [79]. Although many compounds have been studied, few have made it as far as phase III study.

Apremilast inhibits phosphodiesterase 4 (PDE4), one of 11 phosphodiesterases widely expressed in a heterogeneous array of cell types, and it hydrolyses and degrades cyclic AMP [80,81]. PDE4 is involved in modulating inflammatory processes downstream from protein kinase A, changing the cytokine profile in varying cell types [82]. Apremilast inhibits the production of TNF-α, IL-12, as well as the chemokines CXCL9, CXCL10 and CCL4, in human peripheral mononuclear cells stimulated with bacterial lipopolysaccharide. In T cells, apremilast decreases the expression of IFN-γ, and in neutrophils inhibits the production of IL-8 [83,84].

The PALACE Phase III trials compared two doses of apremilast with placebo in those with active disease despite prior treatment with DMARDs or biologics, and each demonstrated better performance than placebo in reaching ACR20 [85]. Two-year follow-up data presented recently, in open label extension for...
The PALACE3 trial demonstrated sustained ACR20 responses [86]. There were no new safety concerns, although tolerability due to GI disturbances can be an issue in the short-term, and there was a less pronounced effect on dactylitis and enthesitis when compared with ustekinumab and secukinumab [87].

There is a biological basis that tofacitinib may be beneficial in PsA, with recent data demonstrating that it inhibits proinflammatory mechanisms in both in vitro and in vitro synovial models [88]. There are currently three clinical trials of tofacitinib in PsA, and it is hoped that they will validate the JAK-STAT pathway as a relevant target in PsA. Tofacitinib has been shown to inhibit IL-4 dependent Th2 differentiation. It also interferes with Th17 differentiation, inhibiting the expression of the IL-23 receptor and the signature cytokines of Th17 cells including IL-17, and IL-22, when naive T cells were stimulated with IL-6 and IL-13., but this was rescued when the same cells were stimulated in the presence of TGF-β. In a model of established arthritis, tofacitinib improved disease, inhibiting the production of inflammatory mediators and suppressing STAT1-dependent genes in joint tissue [89]. There is very limited data on the effect the small molecular inhibitors have on radiographic progression in the context of PsA. The biology of small molecular inhibitors is complex as their targets often represent ubiquitous intracellular signaling pathways that are incompletely understood and are essential for both physiological and pathological processes. Some concern exists about how truly selective these molecular inhibitors are, and about the safety in relation to both serious infection and malignancy risks.

As outcomes such as resolution of dactylitis and enthesitis have been reported as secondary outcomes in the trials of both the biologic agents and small molecular inhibitors, it is not possible to draw conclusions as to which agent performs best for patients with a high burden of a specific presentation of the disease. Only ustekinumab has data on radiographically detected bone changes in Phase III trials [62].

Conclusion
PsA is an important disease and is still underrecognized. Our recent advances in understanding the underlying pathophysiology of this disease have contributed to our understanding of inflammatory biology in general. The recognition of the differences in cytokine biology, as well as in molecular networks between differing inflammatory diseases, underscores the inadequacies of current disease taxonomy. A complete understanding of these networks, and knowledge of the important nodal differences between them, promises to allow better prognostication, the identification of better biomarkers, as well as more rational selection of treatments. Mapping these networks may also reveal further putative targets.

For now, however, the emergence of drugs targeting IL-12/23 and IL-17 represents the most significant advance in recent years, and together with the more recent emergence of apremilast as a proven agent, these agents represent an exciting dawn of a new age in PsA.

Future perspective
Although discreet phenotypes of PsA are well described based on their clinical features, a more meaningful categorization of these may be achievable by a fuller understanding of the disease network(s). It no longer makes sense to pursue the established clinical nomenclature, and this should be dispensed with in favor of describing diseases by their disease network. An understanding of the importance of the cytokine hierarchy is the first step toward this more meaningful classification system.

It is also notable that current strategies at identifying targets in PsA are still focusing on treatment, rather than prevention. Isolating the biological processes around the time of loss of self-tolerance, may introduce the possibility cure, or even prevention in the future.

What is clear is that for the moment, physicians and patients must employ a treatment strategy that is rational, and evidence-based, utilizing therapies that are already available and maximizing the benefit that these can offer. Unfortunately, there is a dearth of evidence to inform physician. For example:

- Which nonbiological DMARD should be commenced as first line therapy.
- Whether to switch to biologic therapy after failure of a single nonbiological DMARD, or add/change another DMARD.
- What novel agent is best (lack of head-to-head trials).

However, new evidence suggests that even with the currently limited (though expanding) armamentarium, regular review using an aggressive treat-to-target strategy in PsA, results in better outcomes [90].

Executive summary

- A significant number of patients with psoriatic arthritis do not respond adequately to TNFi.
- PsA is an inherently destructive disease, which causes articular changes early in the disease course and results in disability, with patients reporting similar HAQ scores to RA patients.
- The number of targets therapeutically exploited in PsA has failed to keep pace with those in RA.
- A novel approach to classification and nomenclature in describing rheumatic diseases is required. This must take account of new developments in our understanding of rheumatic diseases, as technologies advance and provide a more complete understanding of disease molecular networks. Such a system must integrally apply a biologically meaningful template to describe disease.
- Undoubtedly the most important development in our understanding of the pathogenesis of PsA concerns the IL-17 inflammatory pathway. There are clearly important differences in the nature of the inflammatory process in PsA when compared with other inflammatory conditions such as RA, and it is necessary to investigate these further to fully understand the disease network.
- The IL-23/-17 pathway is an attractive target in PsA because the downstream molecules all participate in at least one of the key pathological features of PsA.
- New agents will hope to tackle the characteristic pathological new bone formation which is peculiar to the spondyloarthropathies, and leads to deformity and disability.
- There is likely significant functional redundancy in the pro-inflammatory cytokine networks, leading to similar results in inflammatory indices and other outcomes between TNFi and inhibition of novel molecular targets such as IL-17.
