Insulin pump therapy in youths with Type 1 diabetes: uptake and outcomes in the ‘real world’

Rayzel Shulman, Mark R Palmert & Denis Daneman*

Insulin pump use in youths with Type 1 diabetes is increasing steadily, especially in jurisdictions that provide universal funding for the cost of the pump and related supplies.

Discontinuation rates are low and are related to patient factors, such as older age, female sex and higher hemoglobin A1c at 12 months after pump start.

In cross-sectional studies, glycemic control is similar in patients using insulin pumps compared with injections. Many longitudinal studies show an improvement in hemoglobin A1c within the first year of starting pump therapy; however, it appears that hemoglobin A1c increases back toward baseline thereafter.

Results on the impact of pump therapy on the rate of hypoglycemia are mixed.

Overall, the rate of diabetic ketoacidosis (DKA) does not appear to be increased in patients using pump therapy; however, most episodes of DKA occur within the first year of pump use, suggesting a need for interventions targeting initial pump education and clinical support systems.

Potential advantages of pump therapy must be balanced against the potential burden of increased cost and the risk of DKA in individual patients.

In order to study the impact of patient, center and jurisdictional-level factors on diabetes-related outcomes for youths with Type 1 diabetes using insulin pumps, there is a need for high-quality data collected systematically at a population level.

The failure to demonstrate significant advantages of pump therapy should not condemn this approach to treatment, but rather serve as an impetus to improve our understanding of how best to apply this technology, and to redouble our efforts to develop a closed-loop system.

SUMMARY A critical review of the literature about insulin pump therapy for youths with Type 1 diabetes in ‘real-world’ settings was performed. MEDLINE and EMBASE databases were searched for English language papers published between 2006 and August 2011 using terms for Type 1 diabetes, diabetic ketoacidosis, insulin pumps and children. We identified 263 papers and 22 met our inclusion criteria. There is an increasing proportion of youths with Type 1 diabetes using pumps and discontinuation rates are low. Glycemic control tends to.

review
Shulman, Palmert & Daneman

Current management for individuals with Type 1 diabetes (T1D) is largely informed by the results of the Diabetes Control and Complications Trial (DCCT), a randomized controlled trial, and the Epidemiology of Diabetes Interventions and Complications, the long-term monitoring of subjects recruited into the DCCT. The DCCT demonstrated unequivocally that onset and/or progression of the long-term micro- and macro-vascular complications of diabetes could be reduced by approximately 50% by providing intensive insulin therapy through multiple daily injections (MDI) or by continuous subcutaneous insulin infusion (insulin pump) [1,2]. Although these data were derived from individuals 13–39 years of age at recruitment into the study, the findings have been extrapolated to all individuals with T1D, a reasonable assumption in the younger age group too, where natural history studies show that the onset of early diabetic nephropathy, for example, is related to preceding glycemic control [3].

While adults with diabetes generally accept MDI regimens, their acceptability and success in pediatrics has historically been lower [4]. The direct cost of intensive therapy provided by insulin pump in children is estimated to be twice that required for MDI, depending on the local costs and practices [5]. A systematic review and meta-analysis of randomized controlled trials comparing pump to MDI in a total of 165 children with T1D found a modest improvement (0.24%) in hemoglobin A1c (HbA1c) in favor of pump therapy [6]. Such evidence was used to support a combined statement by the European Society for Paediatric Endocrinology, the Pediatric Endocrine Society and the International Society for Pediatric and Adolescent Diabetes recommending insulin pump therapy as an alternative to MDI for specific clinical indications and when appropriate support personnel are available [7].

The incremental costs of pump therapy meant that, until recently, its use was primarily restricted to those who could pay for it independently and those with private insurance. Responding to public and professional interest in the insulin pump’s potential for optimizing glucose control and improving quality of life, some government programs have started to provide funding to cover the cost of pump therapy for youths with T1D [8].

Increased use of the pump may lead to widespread benefit; however, it may also have the potential for harm. For example, diabetic ketoacidosis (DKA) can arise in just 5 h if the pump’s continuous insulin infusion is interrupted [9]. Furthermore, it may also add to the cost of healthcare without clear benefit. Existing evidence of efficacy has been generated in controlled settings with ideal support systems that may not accurately reflect the general pediatric population with T1D under ‘real-world’ conditions.

Differences in uptake and outcomes of insulin pump use in children and adolescents between countries and within countries may be related to funding arrangements, eligibility criteria for initiating and discontinuing pump therapy, center resources and healthcare provider attitudes and expertise. Furthermore, given the increased demand for pump training and clinical follow-up, the quality and thoroughness of the education and additional supports that families need to facilitate effective utilization may be different compared with when it was provided for fewer and more highly selected patients.

Objective
To determine the uptake, discontinuation, safety and effectiveness of insulin pump therapy for youths with T1D in real-world settings.

Methods
For our MEDLINE search, we used a combination of MeSH and free text terms for (diabetes mellitus, Type 1/ or diabetic ketoacidosis/) AND Insulin Infusion Systems/ AND All child (0–18 years) AND English AND 2006 to present. We used a combination of EMBASE descriptor and free text terms for (insulin dependent diabetes mellitus/ or diabetic ketoacidosis/) AND (infusion pump/ or infusion system/) AND (limit to (infant <to one year> or child <unspecified age> or preschool child <1 to 6 years> or school child <7 to 12 years> or adolescent <13 to 17 years>) or ((infan* or child* or teen* or adolescent* or
Insulin pump therapy in youths with Type 1 diabetes: uptake & outcomes in the ‘real world’ REVIEW

The reference lists of all included studies were also reviewed to identify any relevant publications. Eligibility criteria were:

- Studies had to include individuals under the age of 18 years;
- Subjects with a diagnosis of T1D treated with an insulin pump;
- Nonexperimental studies in real-world settings.

Studies were excluded if participants were pregnant or had non-T1D. Outcomes assessed were pump uptake, discontinuation, glycemic control, hypoglycemia and/or DKA. Studies were categorized by study population as either population-based or clinic-based and also on the basis of availability of funding to cover the cost of the pump. The quality of each report was assessed by identifying study limitations and potential sources of bias.

Results

The search strategy for MEDLINE without Revisions <1996 to August Week 4 2011> retrieved 247 references, of which 246 were unique and not duplicated in our other searches. The search strategy for EMBASE <1980 to 2011 Week 34> retrieved 32 references, of which 17 were unique and not duplicated in our other searches. We identified 18 studies from our search that met inclusion criteria. Four additional studies were identified from the reference lists of included studies [10–13]. The characteristics of included studies are described in Table 1.

Eight of the 22 included studies report pump uptake (Table 4) [10,17,19,22,23,28–30]. Pump uptake reported in studies set in jurisdictions that provide universal funding for the cost of the pump, ranges from 11.0 to 30% [17,19,22,23,29] compared with 14–62.9% in studies set in jurisdictions that do not universally fund the cost of the pump [10,28,30]. Not all jurisdictions that provide universal funding cover the full cost of pump therapy. The study with the highest rate of uptake, 62.9%, is set in a clinic-based population where there is no universal funding for the cost of the pump and the mean household income is above the state and national averages [28]. In the US studies, pump use is associated with higher household income, being Caucasian, having private healthcare insurance and higher parental education [10,28,30]. Pump use has increased over time in jurisdictions that provide universal funding [17,19,29]. In one population-based study from France, there is no significant relationship between uptake and academic affiliation or the size of the center; however, there is variability in uptake between centers ranging from 1.3 to 53% [19].

Discontinuation

Six studies report on pump discontinuation rates and they range from 3.2 to 18% (Table 5) [13,18,21,23,27,31]. Older age [13,18,21,31], female sex [13,18,21,31], more advanced pubertal status [21,31], higher HbA1c at pump initiation [13], higher HbA1c at 12 months after pump start [21,27,31], lower frequency of blood glucose monitoring [31], single-parent family [31] and a higher rate of severe hypoglycemia (SH) in the first year of pump use [31] are factors that were found to be associated with discontinuation. Discontinuation rates do not appear to be related to whether there is universal funding or not: 7.2–18% [21,27,31] in jurisdictions that do not provide universal funding for the cost of the pump and 3.2–11.3% [13,18,23] in those that do.

Glycemic control

Six population-based studies [10,11,14,15,17,18] and 11 clinic-based studies [12,20,22–28,30,31] report on glycemic control (Table 6).

DKA: Diabetic ketoacidosis; DM: Diabetes mellitus; ED: Emergency department; MDI: Multiple daily injections; T1D: Type 1 diabetes.
The mean HbA1c of youths on pumps reported in cross-sectional population studies was 8.0% in two studies [10,14], and 7.2–8.4% in clinic-based studies [10,14,20,22,28,30]. Eight studies found that HbA1c improves within the first year after pump start [11,12,22,23,25,27]. However, of those that followed patients for more than 1 year, three studies found that HbA1c increases after the first year of pump therapy [12,23,26], while two found a sustained improvement in HbA1c over time [25,27]. In youths starting on insulin pumps within 4 weeks of diagnosis of T1D, there is no significant difference in HbA1c between those on pumps compared with MDI 1 year after pump start [15].

The range of mean HbA1c levels reported by studies set in a jurisdiction that provides funding for the cost of the pump is no different from those in which there is none: 7.6–8.0% [14,22] and 7.2–8.4% [10,20,28,30], respectively.

Factors found to be associated with poorer glycemic control are older age [10,14,22,24,25], longer duration of T1D [24,25] and higher baseline HbA1c [24]. Two studies report that those with higher baseline HbA1c levels have the biggest improvement in HbA1c on the pump [23,25].

### Diabetic ketoacidosis

Five population-based studies [10,14–17] and four clinic-based studies [12,23,25,27] report the rate of DKA. The rate of DKA in studies ranges from 0 to 22 episodes per 100 patient-years [10,12,14,15,17,23,25,27]. In two studies, the rate of DKA is higher after pump start, compared with before pump start [25,27] and in two other studies, it is higher in those on pumps compared with those on insulin injections [15,17]. The number of episodes of DKA was found to be highest within the first year of pump use [12,17].

By contrast, one study reports a lower rate of DKA in patients on insulin pumps compared with injections [15] and another reports that, after adjusting for confounding factors, those who used a pump were less likely to be hospitalized compared with those on injections [10]. HbA1c was found to be higher in those with DKA in one study [14] and lower in another [27]. The range of the rate of DKA is 0–22 episodes per 100 patient-years in jurisdictions that provide funding for the cost of pump [12,14,15,17,23,25] compared with 3.98 episodes per 100 patient-years in one study set in a jurisdiction that does not fund the cost of the pump [27].

### Hypoglycemia

The rate of hypoglycemia associated with seizure or loss of consciousness in patients on the pump ranges from 0 to 7.96 events per 100 patient-years [11,12,14,15,27]. There is a significant reduction in the rate after pump start in some studies [11,27] and no change in the rate after pump start in others [10,12]. The rate of hypoglycemia in the first year after pump start was found to be higher in patients who eventually discontinued pump therapy compared with those who continued [31]. Of the studies set in jurisdictions that universally fund the cost of the pump and report the rate of hypoglycemia before and after pump start, one reports a reduction in the rate of hypoglycemia [41] and the other reports no reduction in the rate of hypoglycemia [12].

The rate of hypoglycemia requiring assistance from another person ranges from 5–16 episodes per 100 patient-years [15,23]. In patients that started pump therapy because of severe hypoglycemia (SH; requiring help from another person), the rate of SH fell from 52.1 to 24.8/100 patient-years [11]. SH causing unconsciousness or convulsions is associated with a higher insulin dose in one study [14].

### Discussion

#### Uptake

The US studies vary in their estimates of uptake. A population-based US study reports that 22% of youths with T1D are using pump therapy [30], while one clinic-based study reports that 62.9% use pumps [28] and the other reports 14% [30]. All three studies agree that pump therapy use is associated with higher household income, being Caucasian, having private healthcare insurance and higher parental education [10,28,30]. In a clinic-based study in the USA, having private healthcare insurance and higher frequency of blood glucose monitoring was found to be significantly correlated with insulin pump use among adolescents with T1D [32]. Therefore, discrepancy in uptake between US studies is likely to be a reflection of the characteristics of the patient population and the practice patterns of healthcare professionals.

Physician recommendation to initiate pump therapy is probably also influenced by clinical guidelines, as well as by family preferences and physician attitudes [33]. Differences in uptake between and within countries, regardless of the model of pump funding, may be related to the overall organization of diabetes care, eligibility

criteria for starting pump therapy and center resources and expertise.

In jurisdictions where there is either partial or full universal funding for pumps, these factors are also likely to influence patterns of uptake. The socioeconomic status (SES) and parental education level of patients using pumps may differ compared with those not using pumps, despite both groups being eligible to receive partial or full universal government funding. Even in the context of universal funding, uptake varies widely between jurisdictions and between centers within jurisdictions [19,22]. Although there is discussion about the role of supportive healthcare services in determining uptake, there are no consistent findings about what specific factors may explain the disparities. Studies have found no significant association between academic affiliation, center size or model of care and the rate of pediatric insulin pump uptake [19,34].

There has been an increase in pediatric pump use over time in jurisdictions that provide universal funding [17,19,29]. In the Province of Ontario (Canada), there are approximately 8000 children and youths with diabetes. In 2010, approximately 3000 youths with T1D were enrolled in a government-funded insulin pump program. Therefore, we estimate that between 35 and 40% of youths with T1D in Ontario are using an insulin pump. The proportion of youths using insulin pumps in Ontario may be higher than the current proportion of youths in other jurisdictions because Ontario provides 100% universal funding, compared with some others that provide only partial funding. SES and parental education of youths on pumps in Ontario may be slightly more diverse compared with other populations in which the cost of pump therapy is only partially or not universally funded. However, there are still likely to be differences in these patient level factors between those using pumps compared with those on injections within Ontario. There is a gap in knowledge about the characteristics and diabetes-related outcomes of youths using insulin pumps in the real world that merits further investigation.

### Discontinuation

Discontinuation rates of insulin pump therapy among youths with T1D in real-world settings are low. The range of discontinuation rates reported in studies set in jurisdictions that differ in their funding arrangement for insulin pumps overlap. Because these studies include heterogeneous patient populations, one would have to account for the patient-level factors found to be associated with higher rates of discontinuation (see results section) in order to comment about the effect of the funding arrangement for pumps on discontinuation rates. It is unlikely that the model of insulin pump funding alone significantly affects the patient-level characteristics of pump users within a jurisdiction, although future study is required to confirm this hypothesis. Other center-level and physician-level factors, such as eligibility criteria, the availability of 24 h clinical support and physician attitudes and beliefs about pump therapy, probably play an important role in the selection of patients who initiate and discontinue insulin pumps.

A study set in Austria, a country that universally funds the cost of pumps, explored the reasons for discontinuation of pump therapy. This qualitative study included physicians who prescribe pump therapy in children and youths,

and found that when pump discontinuation was requested by the patient, it was mostly owing to nonmedical reasons, while if it was physician initiated, it was because the patient was not compliant or that clinical values had deteriorated [22]. In the same study, patients with T1D who were former pump users reported issues related to the catheter and social/psychological factors (such as visibility and the pump feeling like a foreign body) as reasons for discontinuing pump therapy. Technical problems with the pump or worsening glycemic control were not reported by patients to be important factors in the decision to stop pump therapy.

Other physician-level and diabetes center-level factors may also be important in the selection of patients for insulin pumps. These factors were not consistently reported in the included studies, and therefore we cannot comment on the influence of these on discontinuation rates. There is a lack of evidence about the effect of eligibility criteria and other center-level factors, such as the availability of 24-h clinical support on the rate of pump discontinuation. Modifiable factors identified in our study that were associated with discontinuation are higher HbA1c at 12 months after pump start, lower frequency of blood glucose monitoring and a higher rate of SH in the first year of pump use. These may be important risk factors to identify in pump users so that interventions can be planned in order to reduce the future rate of pump discontinuation.

### Glycemic control

The range of mean HbA1c of youths on insulin pumps in studies in this review (7.2–8.4%) is similar to that of a large population-based sample of youths with T1D on all insulin regimens reported in a study from the Hvidøre Study Group (8.2 ± 1.4%) [35]. This study is an observational, multicenter, cross-sectional study involving 21 pediatric diabetes centers from 19 countries in 2005. The Hvidøre data suggest that in the real world, glycemic control is similar in those using insulin pumps and injections. Although overall improvement in glycemic control is not observed, it does not appear that glycemic control deteriorates among pump users.

In the two studies that found a sustained improvement of HbA1c over time, there were a decreasing number of patients followed over time [25,27]. Nimri and colleagues report that HbA1c levels continued to improve over the first 3 years after pump start. They present data for 279 patients at 1 year after pump start, but for only 81 patients at 3 years after pump start [25]. Similarly, Scrimgeour and colleagues report improvements in the change in HbA1c levels from 1 year prior to pump start at yearly intervals until 8 years after pump start. They report

DKA: Diabetic ketoacidosis; HbA1c: Hemoglobin A1c.
Having a higher baseline HbA1c has been associated with the biggest improvement in HbA1c on the pump [23,25]. However, having a higher baseline HbA1c is also associated with discontinuation [13]. An explanation for this finding may be that those with higher baseline HbA1c who continue pump therapy, are able to improve their glycemic control; however, there are probably many youths with a high baseline HbA1c who discontinue pump therapy as they continue to struggle with the management of their diabetes.

As more jurisdictions provide funding for the cost of the pump, the population characteristics of pump users may change to include a slightly wider range of SES. The extent to which this change will occur is probably related to whether or not the funding is universal, partial or full, and also on the criteria for pump eligibility and other center-level and physician-level factors. Whether these changes will affect treatment outcomes is unclear. Two Australian studies have examined glycemic control in government subsidized pump users. Thong and colleagues report that 10 months after starting pump therapy HbA1c levels fell significantly in the group.

T1D: Type 1 diabetes.
with private health insurance-funded pumps but not in the group with public hospital-funded pumps [36]. Another Australian study examining the outcomes of 17 youths with T1D who are using subsidized pumps found an improvement in HbA1c 10 months after pump start compared with the 12 months prior to pumps start [22]. Six of the 17 patients followed at this particular center received funding for their pumps as a result of grants and community fundraising and the remainder received government financial assistance that does not cover 100% of the cost of the pump [22]. This study population may have been more motivated and intensively supported by the diabetes healthcare team. Increased use of the pump by less motivated patients potentially increases the risk of missed boluses, the biggest barrier to optimum use of the pump [37].

**Diabetic ketoacidosis**

As the uptake of pediatric insulin pumps increases, it is important to consider the impact of increased use on the rate of DKA, a serious and potentially life-threatening complication. Results are mixed regarding the rate of DKA in pump users compared with those on insulin injections (see Table 7). Some studies found a rate of DKA in pump users that is higher than in those using insulin injections. One study found a trend toward a higher rate of DKA after pump start in the prepubertal group [25]. Furthermore, in two studies, the rate of DKA was higher within the first year after starting pump therapy [12,17]. This finding suggests that interventions targeting the education of patients starting pump therapy and/or the availability of clinical support for new pump patients may be able to reduce the risk of DKA in the period immediately after pump start.

DKA: Diabetic ketoacidosis; f/u: Follow-up; HbA1c: Hemoglobin A1c; MDI: Multiple daily injections; SD: Standard deviation; SE: Standard error; T1D: Type 1 diabetes.
The results in our study about differences in the rate of DKA in pump users depending on whether or not the cost of the pump is funded are mixed. We do not observe a higher rate of DKA in pump users in jurisdictions that fund the cost of the pump compared with those that do not. Like other outcomes, we need to identify the factors associated with DKA in youths using pumps and control for those, before we can assess the effect of the funding arrangement for pumps on the rate of DKA. However, there is a lack of data on the factors that predispose youths using insulin pumps to DKA in the real world. Only two studies report on the association of HbA1c with DKA in pump users and the results are conflicting [14,17].

Another concern is that, as universal funding for the cost of pumps becomes more widespread, the patient characteristics of youths using pumps may change to include a group that is less motivated and therefore may be at a higher risk for complications of T1D, including DKA [38,39]. Further studies are required to understand the evolving characteristics of youths using insulin pumps and diabetes-related outcomes.

### Hypoglycemia

The impact of pump therapy in youths with T1D on the rate of hypoglycemia in real-world settings is mixed (Table 8). None of the studies found an increase in the rate of hypoglycemia in those using insulin pumps, suggesting that for this outcome, insulin pump use in real-world settings is safe. However, the evidence does not show a reduction in the rate of hypoglycemia, a theoretical benefit of insulin pump therapy. Hypoglycemia is a difficult outcome to measure because most studies rely on self-reporting to identify episodes of hypoglycemia, and the definition of hypoglycemia differs between studies. The heterogeneity of study settings and designs, ascertainment of hypoglycemic events and the small number of hypoglycemic episodes reported makes it difficult to draw any generalized conclusions about this outcome. It is possible that individual characteristics (e.g., loss of early warning symptoms of hypoglycemia with lower HbA1c level) may lead to higher or lower risks of hypoglycemia.

### Conclusion

Data from studies set in the real world suggest that there is an increasing proportion of youths

with T1D using pump therapy. Overall, discontinuation rates are low and are related to some specific patient-level factors. Glycemic control reported in cross-sectional studies is similar in groups using insulin pumps compared with injections. HbA1c tends to improve in the first year after starting pump therapy and reverts toward baseline levels thereafter. With regards to acute complications of T1D, including DKA and hypoglycemia, the evidence is mixed. In general, there is no overwhelming evidence to suggest that the rate of hypoglycemia is different with insulin pump therapy. However, there are some reports of an increased frequency of DKA in pump users, especially within the first year after starting pump therapy. This finding is important since this adverse outcome is potentially preventable by identifying users at the highest risk for DKA and implementing interventions geared at initial pump education and ongoing clinical support.

It is difficult to assess the quality of real-world studies with the same rigor as randomized controlled trials; nonetheless, data from multicenter and population-based registries provide important evidence about the effectiveness of pediatric pump therapy because the results are likely to be externally valid. Although true for multicenter studies too, it is particularly important that single-center studies are interpreted in the context of the characteristics of the study population, the local funding arrangement for insulin pumps and the characteristics of the center providing care.

Based on available real-world evidence, the clinical benefits to pump therapy are not uniformly demonstrated, and it remains possible that the rate of DKA is higher among pump patients. There are differences in results among centers, and a better understanding of the bases of those differences might further clarify the pros and cons of pump therapy. Despite these uncertainties, there has been an increase in the use of insulin pump therapy for T1D in youths.

When considering pump therapy, potential advantages, such as increased flexibility in lifestyle and patient satisfaction, precision of insulin delivery and reduction of number of injections, must be balanced by potential risks of treatment, including DKA, deterioration of glycemic control due to missed boluses and skin damage and infection. Thus, there is a need to further explore the role of possible factors such as practice guidelines, industry pressure and

**Future perspective**

Understanding how complex health-care interventions, such as insulin pumps, are implemented into the structure of health-care delivery for youths with T1D is important for informing strategies to improve outcomes of pediatric insulin pump therapy. However, the success of these interventions depends on the capacity of the system to provide adequate support for pediatric pump users beyond the time of pump therapy. Pediatric insulin pump therapy is a complex intervention that requires both medical and financial arrangements to ensure that these interventions are accessible and feasible. The failure to demonstrate significant advantages of pump therapy over MDI therapy in the hope of 'closing the loop' that may influence best health-care providers to recommend pumps as best therapy or for families to request it. Healthcare systems must also assess the validity of these potential factors associated with increased use of pump therapy over MDI therapy and assess the validity of these potential factors associated with increased use of pump therapy, as well as ongoing support for insulin dose adjustments and troubleshooting pump problems. The potential for infant and childhood outcomes, such as the model of care, funding for devices and supplies, is highly likely that these factors differ between centers and influence pump uptake and outcomes. The scope of center and jurisdiction-level factors, such as the model of care, funding for devices and supplies, is high.
children and youths with T1D should not condemn this approach to treatment, but rather serve as an impetus to improve our understanding of how best to apply this technology, and to redouble our efforts to develop a closed-loop system, which removes the vagaries of individual decision-making from the treatment regimen.

Papers of special note have been highlighted as:

- of interest
- of considerable interest

- Systematic review and meta-analysis of randomized controlled trials comparing pump to multiple daily injections in a total of 165 children with Type 1 diabetes.

- Limitations include a relatively short follow-up period (maximum of 12 months), small sample sizes and methodological criticisms of included studies.

- Cross-sectional retrospective study of 1086 youths using insulin pump therapy in 30 centers from 16 European countries and Israel under ‘real-world’ conditions.

- Prospective multicenter study of 11,710 adults and children on insulin pumps examining pump discontinuation using data from a diabetes database established since 1990 in Germany and Austria.
Results of a French national survey in 2001 and 2007 examining the frequency of pediatric insulin pump use. Future results from this survey will evaluate the decision-making criteria that influence the initiation of insulin pump therapy in Type 1 diabetes pediatric patients.

Retrospective chart review of 17 children using ‘donor’ insulin pumps examining glycemic control during the 12 months before starting pump therapy and the most recent HbA1c level. Limitations are that this is a small sample size from a single clinic dedicated to raising funds to fund the cost of pediatric insulin pumps.
